Lecture - 9
Multi-Step Methods (Explicit)

Good morning, till last class we have discussed single steps methods to solve initial problems. And we have reviewed some of the methods and then try to attempt some problems. So, in the single steps methods what we have seen to compute value at a particular lid point. We need one value at one past point. So this is single steps method. That is means to compute y of x n plus 1, we need a y of x n . So, as the name suggest as in multi step method maybe we could expect that instead of one past point we need a several past points. So, the further these multi steps methods can be classified into different varieties. So, let us look at into these multi step methods.

(Refer Slide Time: 01:25)

So, multi step methods. So, what it does this uses past values of y of x and or y dashed of x to construct a polynomial that approximate the derivatives, and extrapolates into the next intervals. So, what it does? It uses past values of y x and or. That means could be sometimes y dash or sometimes just y alone. To construct a polynomial that approximates the derivatives and extrapolates into the next interval.

So, what is the general, the general methods? y_{n+1} plus h times some processor ϕ x_{n+1} plus x_{n-k+1} then the derivative terms. So, look at it the value of $n+1$ stage demands values at n , $n-1$, $n-k+1$. Plus also demands the derivative values these points. So, this is more general case right? So, this can also be put it in a little different sums as follows.

(Refer Slide Time: 04:56)

© CET
I.I.T. KGP

$$y_{n+1} = a_1 y_n + a_2 y_{n-1} + \dots + a_k y_{n-k+1} + h(b_0 y'_{n+1} + b_1 y'_n + \dots + b_k y'_{n-k+1})$$

$$= \sum_{i=1}^k a_i y_{n-i+1} + h \sum_{i=0}^k b_i y'_{n-i+1} \quad \left| \begin{array}{l} y'_{n+1} = f(x_{n+1}, y_{n+1}) \\ \text{---} \end{array} \right.$$

Remarks (1) If $b_0 = 0$, example

$$y_{n+1} = a_1 y_n + a_2 y_{n-1} + b_1 y'_n$$

"Explicit Method"

(2) If $b_0 \neq 0$, example

$$y_{n+1} = 4y_n - 6y_{n-1} + 2hy'_{n+1} + 7hy'_n$$

"Implicit Method"

NPTEL

So, this is functional use at past points plus h . So, explicitly I am writing the ϕ . So, which can be written as... So, here i is 1 to k , here we are including 0 as well. So, for the derivative. So, this the more general method. So, once we write such a general method few remarks. If b_0 is 0. Example if b_0 is 0, example $y_{n+1} = a_1 y_n + a_2 y_{n-1} + b_1 y'_n$, if b_0 that is b_0 . So, look at it what is b_0 is coefficient of y_{n+1}' . And we are trying to compute y_{n+1} . Now what is y_{n+1}' ? X_{n+1} .

So, it demands y_{n+1} that means to compute y_{n+1} right hand side demands y_{n+1} . So, now if b_0 is 0, then the right hand side does not demand y_{n+1} . So, to compute y_{n+1} , y_n , $n-1$, $n-k+1$. And since b_0 is 0 we need from y_n' up to y_{n-k+1}' . So, that means if you know the past values n to $n-k+1$, I can compute y_{n+1} .

Hence this method is explicit method, this method is explicit method. Now if b_0 is non 0. Say example y_{n+1} is say some $4y_n - 6y_{n-1} + 2hy'_{n+1} + 7hy'_n$

plus 7 h. So, look at that. We are computing y_{n+1} and right hand side demands y_{n+1} , because to compute y_{n+1} we need y_{n+1} . So, that means this is implicit method why? Because right hand side... See you are computing y_{n+1} , but right hand side also demands y_{n+1} . So, therefore, this is implicit method. So let us try to discuss explicit methods. So let us start explicit method and try to understand.

(Refer Slide Time: 09:49)

The slide is titled "Explicit Methods" and contains the following content:

- Equation (1): $y' = f(x, y); y(x_0) = y_0$
- Text: "integrating between x_n to x_{n+1} , we get"
- Equation (2): $y(x_{n+1}) = y(x_n) + \int_{x_n}^{x_{n+1}} f(x, y) dx$
- Text: "to evaluate (2), one can approximate $f(x, y)$ by a polynomial that interpolates $f(x, y)$ at k points $(x_0, y_0), (x_1, y_1), \dots, (x_{n-k}, y_{n-k})$ "
- Diagram: A horizontal axis with points x_{n-k+1}, x_n, x_{n+1} marked. Above the axis, a point y_{n+1} is indicated. Ellipses between x_{n-k+1} and x_n indicate intermediate points.

So, explicit methods. So, consider our initial value problem with. Now integrating between one interval that is x_n to x_{n+1} we get. So, what we are done? So, we have integrated between just one interval. So, the method is. Suppose this is x_n , so $x_{n-1}, x_{n-2}, \dots, x_{n-k+1}$. So, the method we are talking about explicit methods, that means to compute y here, so we would like to compute y there. So, we need we need the past points $y_n, y_{n-1}, y_{n-2}, \dots, y_{n-k+1}$ right? So, for that what we are doing we are just integrating between only one step.

Now where are we trying to use the past points? So, the past points look at this. Now we have to approximate f by a suitable polynomial. So, here we will use this past points. So, what we do? To evaluate two one can approximate f of x, y by a polynomial that interpolates f of x, y at k points. What are they? $x_n, y_n, x_{n-1}, y_{n-1}, x_{n-2}, y_{n-2}, \dots, x_{n-k}, y_{n-k}$.

So look, we have to evaluate this integran the integration so integration. So, one can approximate by a polynomial that interpolates f at k point. And what are they? $x_{n-1}, y_{n-1}, x_{n-2}, y_{n-2}, \dots, x_{n-k}, y_{n-k}$.

1, $x_n - k$. So, these are all past points so there is nothing implicit everything is explicit. Now how do we approximate? One you can use forward or backward or difference formulas right? So let us try to use one of them to approximate f .

(Refer Slide Time: 14:36)

we use Newton's backward difference formula of degree $(k-1)$. If f has k constant derivatives

$$P_{k-1}(x) = f_n + \frac{(x-x_n)}{h} \nabla f_n + \frac{(x-x_n)(x-x_{n-1})}{2! h^2} \nabla^2 f_n + \dots$$

$$+ \frac{(x-x_n)(x-x_{n-1}) \dots (x-x_{n-k+2})}{(k-1)! h^{k-1}} \nabla^{k-1} f_n \quad \text{--- (3)}$$

$$+ \frac{(x-x_n)(x-x_{n-1}) \dots (x-x_{n-k+1})}{k!} f^{(k)}(\xi)$$

$\xi \in [x_{n-k+1}, x_n]$

So, we use Newton's backward difference formula of. Well if there are k past points what will be the degree of the polynomial that could be approximated k minus one? Now in order to use this we have to assume the that. If f has k constant derivatives or polynomial of degree k minus 1 will be f_n plus x minus x_n by h delta f_n , x minus x_n , x minus x_n minus 1 factorial 2 h squared. Then the second differences plus. x minus x_n minus 1 n minus k plus 2. This k minus 1 turn h power k minus 1 and this. So this is backward operator where, this is backward operator, so that is this on f_n backward operator. Now plus k factorial and this, this is the reminder term. So, this where f_k is the k th derivative of f evaluate at some ζ in the interval.

So look at it, we have used Newton's backward difference formula and this is given by, this is given by f_n plus x minus x_n by h . This is a first differences second order differences that ((Refer Time: 19.43)) order differences and this is the k minus 1 term. Then k th term is the reminder term that involves derivatives of f_k thought derivative of f . Now our task is that to simplify further and substitute this in the integrant. So before we substitute let us try to simplify this further. So note that you have... See p minus k 1 is a function of x right. So you have this variables x minus x_n your variable is now here x

that is $x - x_n$, $x - x_n$, minus 1. So, 1 so far so we try to introduce change of variable as follows.

(Refer Slide Time: 19:44)

changing the variable in ② by

$$u = \frac{x - x_n}{h}, \text{ we get}$$

$$uh + x_n = x; \quad \frac{x - x_{n-1}}{h} = (u+1)$$

$$P_{k-1}(x_n + uh) = f_n + u \nabla f_n + \frac{u(u+1)}{2!} \nabla^2 f_n + \dots$$

$$\dots + \frac{u(u+1)(u+2) \dots (u+k-2)}{(k-1)!} \nabla^{k-1} f_n$$

$$+ \frac{u(u+1)(u+2) \dots (u+k-1)}{k!} h^k f_n^{(k)}$$

So, what is the change of variable? Changing the variable in three by u equals to $x - x_n$ by h . Look at that. So you have backward Newton difference formula, Newton's backward difference formula. So this is $x - x_n$ by h we are transforming it to new variable u . Hence we try to convert everything in terms of u . So if, note that if this is u what will be $x - x_n$ minus 1. What will be that? Let us see this is... that means $uh + x_n$ is x . So, we need a next term is $x - x_n$ by h . So we need to compute this.

So what will be this to this notation? This will be $u + 1$. So, you can verify. So, hence with this our polynomial become $P_{k-1}(x_n + uh)$ because x is this. Equals f_n approximate u times first difference. So, what could be the next term? Again we go back. See this is $x - x_n$ by h is u , so $x - x_{n-1}$ by h is $u + 1$. Now we have $x - x_n$ minus 1 by h . So that must be $u + 1$.

So $u, u + 1$ by 2 factorial second order differences. Now the next term $u + k - 1$ $k - 1$ factorial, $k - 1$ factorial, this will be $k - 2$ because we need a one previous factorial term. So $u, u + 1, u + 2, u + k - 2, k - 1$ factorial, $k - 1$, f_n plus the next term k factorial, two h power k . Look what did we do?

(Refer Slide Time: 24:25)

we use Newton's backward difference formula of degree $(k-1)$. If f has k constant derivatives

$$P_{k-1}(x) = f_n + \frac{(x-x_n)}{h} \nabla f_n + \frac{(x-x_n)(x-x_{n-1})}{2! h^2} \nabla^2 f_n + \dots$$

$$\dots + \frac{(x-x_n)(x-x_{n-1}) \dots (x-x_{n-k+2})}{(k-1)! h^{k-1}} \nabla^{k-1} f_n \quad \text{--- (3)}$$

$$+ \frac{(x-x_n)(x-x_{n-1}) \dots (x-x_{n-k+1})}{k!} f^{(k)}(\xi)$$

$\xi \in [x_{n-k+1}, x_n]$

$\frac{x-x_n}{h} = u$

We have transform this using variable u so correspondingly one h goes to x minus x_n by h another goes to this. But if you observe there is no h here in this term in the denominator. So, therefore, we have to supply $1/h^2$ and n minus k plus 1 further this term. So that means total how many h ? So, accordingly we get a numerator h power k and the denominator h power k . So, that denominator got adjusted into u , $u+1$ $u+2$ this under the numerator determined.

(Refer Slide Time: 29:40)

$$P_{k-1}(x_n + uh) \approx \sum_{m=0}^{k-1} (-1)^m \binom{-u}{m} \nabla^m f_n$$

$$+ (-1)^k \binom{-u}{k} h^k f^{(k)}(\xi) \quad \text{--- (4)}$$

where $\binom{-u}{m} = (-1)^m \frac{u(u+1) \dots (u+m-1)}{m!}$

using (4) in (2), with $dx = hdu$

So, now further this can be simplified as follows, $P_{k-1}(x) = \sum_{m=0}^{k-1} \binom{k-1}{m} (-1)^m (x-a)^m f^{(m)}(a)$. So what is our new variable now? Its u , u is our new variable. So, this equals $\sum_{m=0}^{k-1} \binom{k-1}{m} (-1)^m (x-a)^m f^{(m)}(a)$. So we have to define where $(x-a)^m$ is? So what we have done we have approximated and we have put it in a simpler form and this is a reminder term. Now what is our concern?

Our concern was to substitute the polynomial that has been approximated into this integrant, which was two. So we have approximated f by using k past points and that was four. So, now what we have suppose to do now using four into with this notation b x will be $h d u$. This is because of the change of the variable. Now when we substitute this in the integrant the expression two reduces as follows.

(Refer Slide Time: 28:11)

$$y^{(n+1)} = y^{(n)} + h \int_0^1 \left[\sum_{m=0}^{k-1} \binom{k-1}{m} (-1)^m (x-a)^m f^{(m)}(a) + (-1)^k \binom{k-1}{k} h^k f^{(k)}(\xi) \right] du$$

Plus h 0 to 1 . So, I will explain why this 0 to 1 . This is the reminder term and the variable is t u . So, why the...

(Refer Slide Time: 29:23)

Explicit Methods

$y' = f(x, y); y(x_0) = y_0$ — (1)

integrating between x_n to x_{n+1} , we get

$$y(x_{n+1}) = y(x_n) + \int_{x_n}^{x_{n+1}} f(x, y) dx$$
 — (2)

to evaluate (2), one can approximate $f(x, y)$ by a polynomial that interpolates $f(x, y)$ at k pts $(x_0, y_0), (x_1, y_1), \dots, (x_{n-k}, y_{n-k})$

$x = x_n + uh$
 $x_n = x_n + uh \Rightarrow u = 0$
 $x_{n+1} = x_n + uh \Rightarrow u = 1$

So, our limits x_n to x_{n+1} . That what was our transformation? Our transformation was $x = x_n + uh$. So, therefore, when x is x_n u is varying from 0 and one x is x_{n+1} so this will be. See when x is x_n this implies u is 0. And when x is x_{n+1} , $x_{n+1} - x_n$ is h .

(Refer Slide Time: 30:30)

$$y(x_{n+1}) = y(x_n) + h \int_0^1 \left[\sum_{m=0}^{k-1} (-1)^m \binom{-u}{m} \nabla^m f_n + (-1)^k \binom{-u}{k} h^k f^{(k)}(\xi) \right] du$$

$$= y(x_n) + h \sum_{m=0}^{k-1} \gamma_m^{(0)} \nabla^m f_n + T_k^{(0)}$$
 — (5)

where $\gamma_m^{(0)} = \int_0^1 (-1)^m \binom{-u}{m} du$

$$T_k^{(0)} = h^{k+1} \int_0^1 (-1)^k \binom{-u}{k} f^{(k)}(\xi) du$$
 remainder — (6)

So, this is so the change of variable brings these limits. So, now this is equals plus h I take the integrand inside summation outside, which is permitted. So, 0 to $k-1$ so some new notation. So I introduce a new notation look this same thing I am writing, where this

has got in. So integrant, integral has gone inside and the differences have retained as it is and this is definitely t k. So that means when the summation has come out what is left integral 0 to 1 minus 1 power n and minus u c m. So that must be therefore, let us defined where.

So, these are some kind of codes equals this. So, where this and this h because h power k there is one h, h power k plus 1. So this is the reminder right? So, try to follow carefully so y x n plus 1 is we have approximated the integrant by polynomial using k past points. And we got a polynomial of degree k minus 1. And that has been substituted in the, in the integrant. So that has been substituted that has a simplified form and these are codes.

(Refer Slide Time: 33:26)

$$y_{n+1} \approx y_n + h \sum_{m=0}^{k-1} \gamma_m^{(k)} \nabla^m f_n \quad (7)$$

Calculating $\gamma_m^{(k)}$: $\gamma_m^{(k)} = \int_0^1 (-1)^m \binom{-k}{m} du$

$m=0, \quad \gamma_0^{(k)} = \int_0^1 du = 1$

$m=1, \quad \gamma_1^{(k)} = \int_0^1 (-1) \binom{-k}{1} du = \int_0^1 u du = \frac{1}{2}$

$m=2, \quad \gamma_2^{(k)} = \int_0^1 (-1)^2 \binom{-k}{2} du = \int_0^1 \frac{1}{2} u(u+1) du = \frac{5}{12}$

$m=3, \quad \gamma_3^{(k)} = \frac{3}{8}$

So now let us simplify further so the approximation is given by. So, after removing the error. I have removed the error time and this approximation. So, this our formula however these codes are to be computed right. So, then the next issue is calculating this codes. So, let us say m 0. So, m 0 because what was our formula our formula was n minus u c m also defined, so using that this will be 1. So, you can compute and to realize that it is this. Now these codes will be computed to get the formula. So, I am doing that we get the formula.

(Refer Slide Time: 36:13)

S. GET
I.I.T. KGP

$$\therefore y_{n+1} \approx y_n + h \left[f_n + \frac{1}{2} \nabla f_n + \frac{5}{12} \nabla^2 f_n + \frac{3}{8} \nabla^3 f_n + \dots \right]$$

⊕

$k=3$, past points $(x_n, y_n), (x_{n-1}, y_{n-1}), (x_{n-2}, y_{n-2})$

$$y_{n+1} \approx y_n + h \left[f_n + \frac{1}{2} \nabla f_n + \frac{5}{12} \nabla^2 f_n \right] + O(h^4)$$

$$\approx y_n + h \left[f_n + \frac{1}{2} (f_n - f_{n-1}) + \frac{5}{12} (f_n - 2f_{n-1} + f_{n-2}) \right] + O(h^4)$$

$$= y_n + \frac{h}{12} (23f_n - 16f_{n-1} + 5f_{n-2}) + O(h^4)$$

So, therefore, because what was the formula? 10 and 0 difference that is f_{n-1} is just 10 gamma 10 just 1 therefore, first term should be f_n . This is then sorry gamma 00 . So, then gamma 10 is half therefore, the next term should be half dell f_n right? So, half of and 5 by 12 the second order differences 3 by 8 . So, this is the general formula now why did we say this is explicit? Look to compute y_n plus we need past points because you see these backward differences it will ask for $n-1$ so on.

Now let us come to specific, so this is more general. So, let us try to fix up the number of points. k is 3 and past points $x_n, y_n, x_{n-1}, y_{n-1}, x_{n-2}, y_{n-2}$. So, suppose these are the past points that means we are approximating the polynomial using this past points. So, we have three points therefore, we expect a quadratic and that quadratic has been integrated to get the formula. So, in this case y_n plus on $1e$ is y_n plus h .

So we have only three points, so we get differences up to second order plus there must be an error right? And what is a error t_k , is if k is three h^4 and this must be evaluated as reminder. So I can write h^4 . Now we have to expand so first all difference it has been backward operator has been expanded. So this is plus. So, we got the approximation and which is explicit and which is multi step. Why multi step? To compute y_n plus we need $n, n-1, n-2$. So let us write down this explicitly.

(Refer Slide Time: 41:02)

I.T. KGP
10

$$y_{n+1} = y_n + \frac{h}{12} (23f_n - 16f_{n-1} + 5f_{n-2})$$

$$T_3^{(4)} = \frac{3}{8} f^{(4)}(\xi) h^4 \text{ error}$$

"Adams-Bashforth method"

$k=4, (x_n, y_n), (x_{n-1}, y_{n-1}), (x_{n-2}, y_{n-2}), (x_{n-3}, y_{n-3})$

$$y_{n+1} = y_n + h \left[f_n + \frac{1}{2} \nabla f_n + \frac{5}{12} \nabla^2 f_n + \frac{3}{8} \nabla^3 f_n \right] + O(h^5)$$

$$= y_n + \frac{h}{24} (55f_n - 59f_{n-1} + 37f_{n-2} - 9f_{n-3})$$

$$T_4^{(4)} = \frac{251}{720} f^{(4)}(\xi) h^5$$

WVTEL

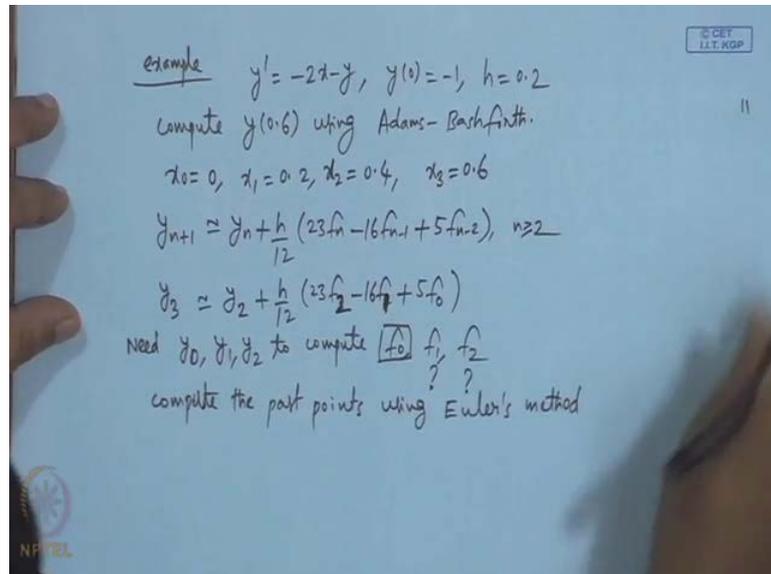

So, this error... So, this an explicit method, which is third, order why? The error is h power 4. So, order of the method is less so that is third order and this has specific name literature Adams-Bashforth method. So this is called Adams-Bashforth method. Now naturally the question comes, can we reduce the error? So, what is the, see here we have derived multi step method and it is third order method. What did we do? We have used past points and how many? Three past points. So, we are approximated by a quadratic.

Now the natural question arises can we improve upon this method? So, what is the idea instead of three past points if you use more past points then we get better polynomial and then that that will be extrapolated right? So, let us try with a four points. Now if you try for four points. So, k equals 4 and the points are. Now I am not explaining the derivation because all that we have to do is simply take our general expression, take our general expression. And since we have one, two, three, four points then we can compute the differences up to thirds order. So by doing so we get, already we have done the codes after third order right? So, we get the following formula.

So this sum simplification $55 f_n - 59 f_{n-1} + 37 f_{n-2} - 9 f_{n-3}$ coefficients are very big. So, competition will be little trades and the error. So, this is another method. So, this Adams-Bashforth method. If you use more points we get the correspondence. Look at that the coefficient are completely different. So, you keep on using more past points and

then you will get a different methods. So, let us quickly look at some problem so that we get some idea.

(Refer Slide Time: 46:03)

So, this is the up compute y of point 6 using Bashforth. So, let us the formula is given. What are we asking to compute y of point six right? What was our x_0, x_1, x_2, x_3 . So, essentially we are asking to compute y_3 , right? Now to compute y_3 your Adams-Bashforth is asking some past point right? y_1, y_2, y_0 of course, see let us look at your method. Adams-Bashforth so y_3 y_2 .

f_3, f_2 sorry f_2 because n is 2, f_1, f_0 . So, to compute f_1 and f_2 we need y_1 and y_2 right? So, remark need y_0 of course, y_1, y_2 , to compute f_0, f_1, f_2 . So, we have y_0 so there is no issue with this, but who will give us f_1 and f_2 . So, in the question itself it should have been mentioned what are the past values require compute using something. Using which kind of method? Of course, using n explicit method then only we can compute. So, let us say it is mentioned compute the past points say using Euler's method. So let us compute using Euler's method.

(Refer Slide Time: 49:47)

$$y' = -2x - y, y(0) = -1, h = 0.2$$

$$x_0 = 0, y_0 = -1$$

$$y_1 = y_0 + h f(x_0, y_0) = -1 + 0.2(-2(0) - (-1)) = -0.8$$

$$y_2 = y_1 + h f(x_1, y_1) = -0.8 + 0.2(-2(0.2) - (-0.8)) = -0.72$$

$$f_0 = 1, f_1 = -2x_1 - y_1 = 0.4$$

$$f_2 = -0.08$$

$$y_3 = y(0.6) = y_2 + \frac{h}{12}(23f_2 - 16f_1 + 5f_0)$$

$$= -0.72 + \frac{0.2}{12}(23(-0.08) - 16(0.4) + 5(1)) = -1.224$$

so, y dashed was... so x_0 is 0 y_0 is minus 1. Therefore, y_1 is so y_0 is minus 1 h is point 2 minus 2 x_0 is 0. So, this is then y_2 h times minus 2 x_1 then minus. So, this is minus point seven 2. So, we got y_1 y_2 using Euler method that means we have all the data, we have y_0 , y_1 , y_2 . Now what was our? Of course we need immediately f_0 so f_0 is, f_0 is minus 1, f_0 is minus of minus 1. So, this is 1 then f_1 is minus 2, x_1 minus y_1 . So, f_1 is point 4 and f_2 , f_2 is minus point not 8. So we have to compute, then y_3 , which is a f point 6. This is given by y_2 plus h by 12 $23 f_2$ minus $16 f_1$ plus $5 f_0$. So, this is h is f_2 minus $16 f_1$ plus 5 . So, we get approximate value, which is minus 1 point 2 2 4. So, what we have done? We need the past values.

So, to compute using Adams-Bashforth we need three past values n , $n - 1$, $n - 2$. And in the question it should be given using, which method one should compute the past values. In the present problem we have used Euler's method the simple. But if you really need better accuracy one should use may be higher order Taylor's method or RK method. So, that will give more accurate results. So you have seen what is the logic we have integrated between one interval and then the polynomial has been fitted with a using k past point.

Now the larger the value of k the better approximation of the polynomial and hence the error will be less. So, we have tried k three and then k four and k three there is a specific name Adams-Bashforth, which is explicit method. And k four also is an explicit method.

Suppose instead of that if the right hand side demands y and plus 1 as well then we end up with something called implicit method. We, try to discuss in the next class these methods.

Thank you have a nice day.
